SAHILWHO / FIELD GUIDE NO. 007

NO ONE SEES THE WHOLE SKY.

COLLECTIVE INTELLIGENCE: HOW MANY MINDS CAN THINK BETTER TOGETHER

A printable companion to the Collective Signal Laboratory. Learn the mechanisms, read the evidence, reproduce the exercise without a screen, and use the group-decision worksheet in a real meeting.

An independent educational exhibit. It is not a psychometric test, a validated forecast model, or an assessment of the people who use it.

THE FIELD GUIDE / HOW TO USE IT

Your route through the evidence

• 1. Read the conceptual field notes before interpreting the numerical lab.

• 2. Try the print alternative: calculate a mean, median, spread and reference error from the six fictional guesses.

• 3. Compare private estimates with peer convergence and a loud anchor. Notice that apparent unity need not improve truth.

• 4. Use the practical protocol and printable worksheet to design a real group decision.

• 5. Follow the source ledger. A published study supports a bounded claim, not a universal rule.

Core distinction

Consensus is agreement among participants. **Accuracy** is correspondence with a credible external reference. A team can gain confidence while remaining inaccurate. This is the central idea of the exhibit.

01. Intelligence beyond a single mind

Collective intelligence names a family of phenomena in which the coordinated activity of multiple people, agents, or information sources produces useful understanding or action. It can mean the accuracy of aggregated estimates, the problem-solving performance of small teams, the quality of a shared knowledge resource, or the ability of a community to govern common resources. These are related but not interchangeable outcomes.

A group can be accurate at estimating a number while being terrible at making a fair decision. A team can collaborate wonderfully on one task but fail on another. A knowledge platform can be broad and productive yet uneven in whose perspectives it includes. The phrase "the crowd is wise" collapses these differences. A more careful question asks: wise about what, under which conditions, compared with which alternative, and measured how?

In experimental work, Woolley and colleagues reported evidence for a group-level performance factor across a range of tasks in small groups. The factor was associated with aspects of interaction such as conversational turn-taking and social sensitivity rather than simply the highest individual test score. That finding is important, but it does not prove a universal numerical intelligence score for every possible group or that every form of collaboration produces a benefit. [3]

02. Four conditions worth protecting

Information diversity. Participants need access to at least partly different evidence, perspectives or methods. If everyone shares the same mistaken source, averaging repeats the same mistake. Diversity is not the mere presence of demographic categories; for a particular task, it also concerns what each person can notice and how each person approaches a problem.

Relative independence. Recording judgments privately before discussion can reduce premature convergence. Independence is rarely absolute. People share educational systems, news feeds and cultural assumptions. The relevant question is whether different estimates carry genuinely separate information rather than copies of one signal.

Useful aggregation. A group needs a defensible way to combine inputs: a median, an average, a vote, a deliberative process, or an expert-reviewed synthesis. A method suited to estimating quantities may be inadequate for resolving ethical conflicts. The algorithm is not neutral if it decides whose evidence counts.

Feedback and revision. A group must be able to encounter consequences, correct errors and protect dissent. If status, fear or punishment prevent members from revisiting an answer, coordination can harden into collective overconfidence. A good process records uncertainty rather than manufacturing consensus.

03. Why difference can be useful

Lu Hong and Scott Page studied a formal model in which problem solvers use different approaches and representations. Under particular assumptions, groups with functional diversity can outperform groups assembled only from top individual performers. The model helps explain why teams benefit from complementary search strategies rather than many copies of the same expertise. It does *not* establish that any randomly assembled diverse group will outperform specialists in the real world. Skill, task structure and collaboration costs matter. [2]

Think of a neighborhood flood-planning team. A drainage engineer may understand runoff, a resident may know which underpass fills first, a street vendor may understand the hours when foot traffic peaks, and a disability advocate may notice evacuation barriers. This is a hypothetical example, not a recorded study. The benefit comes not from disagreement as a fashion statement, but from the discovery of information that would otherwise have remained missing.

Diversity can also create friction. Different vocabularies, status differences and incentives may prevent information from being heard. An inclusive room without equitable influence can retain the appearance of diversity while functionally behaving as a single voice. The relevant design question is how knowledge enters the decision, not merely who appears in the team photograph.

04. Agreement is not accuracy

Independent estimates sometimes benefit from errors that partly cancel. But social influence can compress the visible range of answers without improving the underlying estimate. Lorenz and colleagues experimentally examined this issue and found that even mild information about other participants' estimates could undermine forms of crowd wisdom. Their task and sample do not justify assuming that discussion is always harmful; they show that information sharing changes the statistical properties of judgments and can create false reassurance. [4]

There is an important distinction between *learning* from another person's evidence and *copying* their conclusion. A scientist who revises a claim after receiving better measurements may improve accuracy. A team that shifts toward a leader merely because the leader spoke first may magnify shared error. The lab above deliberately separates those possibilities by modeling imitation without adding evidence.

In the peer-influence condition, all guesses move toward their original group mean. Because moving every value toward the same mean does not change that mean, the crowd looks more unanimous but is no more accurate. In the loud-anchor condition, guesses move toward one observer's value. This can improve or worsen the result depending on whether the anchor was more accurate. Our toy model proves only the arithmetic of its own rules.

05. How should many judgments become one?

There is no universally best aggregator. An arithmetic mean gives every numeric estimate equal weight and can be moved by extreme values. A median is less sensitive to an extreme outlier, but it discards distance information. A majority vote may work for some binary questions under appropriate competence and independence assumptions, but a majority cannot turn a false premise into a fact. Expert weighting may improve predictions where expertise has been independently demonstrated; otherwise it can merely encode prestige.

Hastie and Kameda compared group decision rules in simulation and a behavioral setting, finding that simple rules such as majority and plurality can perform competitively under the conditions they examined. Their result is not a license to settle every governance question by a show of hands. The fairness of the question, the interests affected and minority rights remain separate considerations. [7]

The lab presents mean and median side by side to expose the choice of method. Neither indicator should be mistaken for a confidence interval or the likelihood that a real decision is correct. A narrow spread shows how close the simulated reports are to one another; it does not tell us whether the group shares a common blind spot.

06. Cooperation is an institution, not just a conversation

Shared intelligence also depends on rules: who may participate, how claims are challenged, whether evidence can be audited, and whether people have reason to tell the truth. Elinor Ostrom's work on common-pool resources demonstrated the importance of studying locally developed institutions and the contexts in which collective self-governance can succeed. It belongs beside the psychology of groups because coordination and trust are shaped by incentives and accountable procedures, not only by good intentions. [8]

Consider an online knowledge project. Contributors need clear revision histories, opportunities to question claims, accessible sourcing conventions, and processes to resolve conflict. Without those, scale can become a liability: more contributions might mean more noise or more opportunities for coordinated manipulation. A sensible collective system creates channels to surface disagreement before decisions become irreversible.

Sometimes the best group process is to avoid premature interaction. Collect independent views first, then disclose the distribution, then invite participants to explain their evidence, and only then allow revision. Other tasks require sustained dialogue from the beginning, particularly when participants must define the problem jointly. The procedure should follow the task rather than a universal slogan.

07. When the collective becomes a trap

Selection bias: a large sample is still unrepresentative if certain experiences, communities or expertise are absent. **Correlated errors:** shared sources and incentives produce mistakes that do not cancel. **Information cascades:** early confident statements shift later judgments, even if the early evidence was weak. **Social pressure:** people may conceal doubts when disagreeing costs status or security.

Bad task fit: a popularity vote cannot replace a safety test, consent, legal rights or technical inspection. **Opaque aggregation:** hidden weighting rules can silence certain voices. **Adversarial manipulation:** coordinated participants can manufacture the appearance of independent consensus. **False precision:** a single number may erase uncertainty and the reasons for disagreement.

Kerr and Tindale's review of group performance explains why groups exhibit both process gains and process losses depending on how people coordinate, share information and stay motivated. The same institution can perform well under one set of conditions and poorly under another. It is more useful to identify mechanisms than to sort all groups into "smart" and "stupid." [6]

Not "Did everyone agree?" but "What information would still be missing if everyone agreed?"

CASE FILES / DOCUMENTED EXAMPLES

The ox and the crowd.

Francis Galton analyzed estimates in a weight-guessing competition at an agricultural fair. His 1907 *Nature* article, “Vox Populi,” became an influential example of how aggregated judgments can approach a measurable truth despite large errors in individual answers. Later summaries report a median of 1,207 pounds against an actual dressed weight of 1,198 pounds. [1]

What it teaches: In some quantitative tasks, distributed errors can partly cancel. **What it does not teach:** Any crowd on any question will be accurate. The setting had a clear measurable target and a particular set of contest participants.

A galaxy in many eyes.

Galaxy Zoo invited volunteers to inspect images of galaxies from the Sloan Digital Sky Survey. Lintott and colleagues documented tens of millions of individual classifications by a large volunteer community and compared results with classifications of subsets by professional astronomers. The system used repeated judgments and a structured task rather than assuming that every volunteer had identical knowledge. [5]

What it teaches: Carefully designed distributed work can scale a research task and provide cross-checks. **What it does not teach:** Public votes replace scientific standards, or every question can be resolved by majority classification.

PRINT ALTERNATIVE / REPRODUCE THE LAB

A transparent arithmetic thought experiment

All the observers and measurements below are fictional. The reference value is 64. The purpose is to compare ways that the same initial information can be represented. It does not predict real social behavior.

Observer	Mira	Jun	Asha	Sol	Noor	Ivo
Private guess	42	58	63	70	76	87

Step A: Independent. Add all six estimates and divide by six. The total is 396, so the mean is 66. The median is halfway between 63 and 70, or 66.5. The spread is 87 minus 42, or 45. The mean is 2 away from the fictional reference of 64.

Step B: Peer influence. At 100 percent strength, replace every estimate with the original mean, 66. The mean remains 66, the spread falls to 0 and the error remains 2. A group can appear unanimous without learning anything new.

Step C: Loud anchor. At 100 percent strength, replace every estimate with the first estimate, 42. The mean becomes 42, spread is 0, and error becomes 22. On this invented dataset, convergence amplified error. A different first estimate could move the group closer to the reference instead.

Half-strength formula: new report = (1 - influence) × original guess + influence × chosen target. For peer influence, the target is the original mean; for loud anchor, it is the first included guess. At 60 percent influence, use 0.4 × guess + 0.6 × target.

Two reflection questions

- What information, if any, entered the group after the estimates changed?
- If you were evaluating a real meeting, what evidence would distinguish learning from conformity?

WORKSHEET / DESIGN A BETTER GROUP DECISION

A meeting protocol you can use

1. Exact question and decision deadline:

---

2. Is the question factual, predictive, normative, technical, or mixed?

---

3. What evidence does each participant have independently?

---

4. Which viewpoints, expertise or lived experiences are missing?

---

5. Which aggregation rule is justified, and whose inputs are included?

---

6. What is the strongest objection or alternative explanation?

---

7. What would change our minds? What observation would count?

---

8. Who is responsible for documenting and revisiting the decision?

Boundary: Do not treat this worksheet as a replacement for domain-specific safety standards, professional review, democratic legitimacy or informed consent.

FAQ / SIX NECESSARY QUESTIONS

Is collective intelligence the same as democracy?

No. A democratic procedure allocates political authority according to principles that include legitimacy and rights. Collective intelligence examines how groups process information and solve problems. Voting can be one aggregation method, but factual accuracy is not the only relevant criterion in governance.

Does a bigger crowd always predict better?

No. Size helps when additional participants contribute useful, sufficiently independent information. A large group sharing the same systematic mistake can be wrong together. Selection bias, malicious coordination and poor question design can overwhelm any benefit.

Is disagreement a sign that a team is failing?

Not necessarily. Disagreement can expose distinct evidence and prevent premature closure. Conflict can also become destructive if participants lack shared goals or fair procedures. The productive aim is not perpetual disagreement but a process able to test competing accounts.

Should experts and non-experts receive equal weight?

That depends on the question and independently verified track records. Expertise matters greatly for specialized tasks, but local knowledge and outsider perspectives can reveal blind spots. Weighting should be explicit, justified and open to correction rather than based only on prestige.

What is the difference between consensus and accuracy?

Consensus describes the degree to which people agree. Accuracy compares a claim with a credible external reference or standard. People can be unanimously wrong. The lab demonstrates this distinction through a simple numerical mechanism rather than through a validated social model.

Can AI systems participate in collective intelligence?

Potentially, as tools for generating alternatives, checking references, translating perspectives and processing evidence. But many models may share training data and correlated errors. An ensemble of similarly mistaken AI outputs is not necessarily independent evidence. Human accountability remains essential.
